Before we start with the computation of the several greeks, it is important to recall the Black-Scholes formula for an European call and an European put. Let S_0 be the underlying price at time 0, let r be the risk-free rate, let σ be the volatility of the underlying, let T be the maturity of the option, K the strike price and δ the dividend rate. We then have :

$$call(K, T) = S_0 e^{-\delta T} N(d_1) - K e^{rT} N(d_2)$$

$$put(K, T) = K e^{rT} N(-d_2) - S_0 e^{-\delta T} N(-d_1)$$

with :

$$d_1 = \frac{\ln\left(\frac{S_0}{K}\right) + (r - \delta + \frac{\sigma^2}{2})T}{\sigma\sqrt{T}}$$

$$d_2 = d_1 - \sigma\sqrt{T}$$

FIGURE 1 - Call premium

FIGURE 2 - Put premium

Figures 1 and 2 show the premium of both call and put option for specific parameters ($K = 50$, $\sigma = 20\%$ and $r = 10\%$) with different spot prices and time to maturity. It is quite interesting to know those shapes since the greeks are just derivatives with respect to different parameters. Thus, by observing the slope and convexity of those surface we can imagine the shape of the greeks.

Before we begin explaining each greek, one should be aware that knowing the 3D surface of the greeks, instead of just knowing a 2D representation is very useful in order to understand the greeks of combinations of options. A website is provided with this document ([link](#)) in order to allow everyone to manipulate the greeks in a 3D interactive environment. On this website you can rotate, zoom in and out on each greek and also change parameters of the options in order to better understand how each greek evolve with respect to different parameters (please note that site website is hosted on a free webservice provided by shinyapps.io and that connection could be lost with the server for no obvious reasons, just reload the page and continue what you were doing before being disconnected).

1 Greek letters

One important feature for greeks is to compute the greek of a portfolio. If the portfolio contains different options on the same underlying, the greeks of the portfolio is the sum of the greeks of each option in the portfolio.

1.1 Delta

The delta is the sensitivity of the option price with respect to changes in the underlying price. Therefore we can think of the delta as the slope of the price of the option with respect to the price of the underlying. One can show the following analytic formulas for calls and puts :

$$\Delta_{call} = \frac{\partial c}{\partial S} = e^{-\delta T} N(d_1)$$

$$\Delta_{put} = \frac{\partial p}{\partial S} = e^{-\delta T} (N(d_1) - 1)$$

An alternative way to define the delta, is the amount of shares needed in order to completely hedge a short position in the option with respect to changes in the underlying price. With a short position in a call, we will have losses if the price of the underlying increase. Therefore we are looking to take profit of such an increase by taking a position on the underlying (just in order to hedge the position), and we will buy shares (forward could be used too). Thus the delta will always be positive for a call. The same thinking could be made for a put, and show that the delta of a put is always negative since we sell shares in order to hedge our short position.

Figures 4a and 4b represent the delta for a call and a put in 3D and figure 3 represent the same in 2D. We can see that the delta of a put is just a translation of the delta of a call. We have the two following properties :

$$\Delta_{call} \in [0,1] \quad \Delta_{put} \in [-1,0]$$

It is interesting to note that the delta is much steeper when the time to maturity is low, which means that when an option is at the money with a very short maturity, a little change in the underlying price would bring an important change in the delta (this is the gamma). Therefore performing delta hedging with an ATM option with short maturity is very challenging since the delta is constantly having important variations.

When explaining the delta we gave a solution for performing a delta hedging : taking positions in the underlying of the option with a size equal to the delta of the option (in %). We have to keep in mind that a position is delta hedged only at one point in time, if the underlying price moves, the position is no longer hedged because the value of the delta

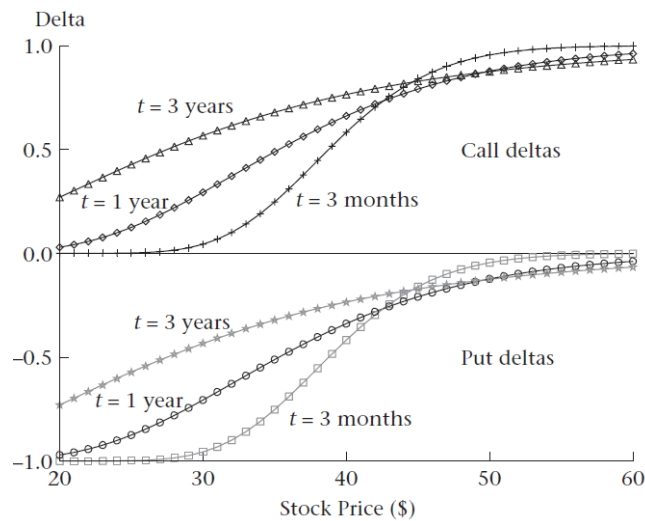

FIGURE 3 - Delta in 2D

FIGURE 4 - Delta surfaces

has changed, we therefore have to take a new position in the underlying in order to be delta hedged again. The process of constantly adjusting its hedging positions is referred to as **dynamic hedging** (opposed to static hedging when the trader only takes one initial hedging position and does not touch it until maturity). Dynamic hedging could be very costly since it needs to make a lot of market orders (remember the commission fees and bid-ask spread), and finding the good period of refreshing for the hedge is the key factor in the cost of a dynamic hedging strategy. If the period is too short, the trader loses too much money in commission

fees, but in the period in too long, then the position in the option is no longer protected by the hedge. A solution would be to be gamma hedged : when one is gamma hedged, the delta will not change a lot and a higher period is possible.

1.2 Gamma

We saw that the delta could have important variation when the strike price is close to the spot price, therefore we need to use the second derivative of the option price with respect to the underlying price (or the derivative of the delta with respect to the underlying price) in order to characterize those variations of delta. One can show that calls and puts have the same gamma and it is given by the following analytic formula :

$$\Gamma = \frac{\partial^2 c}{\partial S^2} = \frac{\partial^2 p}{\partial S^2} = \frac{e^{-\delta T} N'(d_1)}{S_0 \sigma \sqrt{T}}$$

As we already discussed in the section about delta, the delta only have important variation when the maturity is short and when the strike price is close to the spot price we could therefore anticipate the shape of the gamma in figure 6 and we can conclude that gamma hedging is only relevant for ATM options with relatively short maturity.

The gamma of a long position in a call or a put will always be non-negative and the gamma of a short position in a call or a put will always be negative.

FIGURE 5 - Gamma in 2D

One very important point with gamma is its relation with the theta of the option (discussed later in this document) : when the gamma of a position is positive, the theta will tend to be negative, which means that the position will tend to loose value when time passes except if there is an important moove (upward or downward) in the underlying price. The opposite also holds : when the gamma of a position is negative, the theta will tend to be positive, which means that the position will tend to gain value when time passes except if there is an important moove (upward or downward) in the underlying price.

Since gamma is a second derivative of the price with respect to the underlying price, we have to find a financial product which has convexity with respect to the underlying price in order to hedge the gamma. The underlying is not enough because it has not convexity, in most cases we will use another option in order to gamma hedge. Let's consider that we

FIGURE 6 - Gamma surface of both call and put

have a short position on n options (called option 1) with a gamma Γ_1 each, and that on the market, another option is available (called option 2) with a gamma Γ_2 . In order to be gamma hedged, we will have to buy (since we are short option 1 and that the gamma of a short position is negative) $\frac{\Gamma_1}{\Gamma_2}n$ options 2. Our portfolio will then be gamma hedged but not delta neutral, we can make it delta neutral by taking the good position in the underlying (as explained in the previous section). The portfolio will then be delta-gamma hedged. Once again, keep in mind that as every greeks, the gamma may change over time, thus this hedge is only valid for a limited amount of time.

For an ATM option, the gamma will be maximum for a short maturity, but for an OTM option, the gamma will be maximum for a long maturity. As we can see on figure 6, the gamma is very dependant of the time to maturity so performing an exact gamma hedge could be of very little relevance with respect to time. It would make more sens to use a range for the gamma than an exact value.

1.3 Shadow gamma

Nassim Taleb is the one that popularized the notion of shadow gamma. The motivation for such a greek is that when we consider the gamma, we compute a partial derivative and thus suppose that all other parameters stay constant, which is not true in real life. The gamma is meant to measure the price sensibility of the option to big changes in the underlying price and it is easy to understand that an important movement in the underlying price will most likely happen with an important rise of volatility. Therefore considering that volatility stays constant while computing the gamma could lead to huge approximations and such a gamma would not be a good representation of the observed gamma. Such considerations for the variation of volatility for an important variation in the underlying price is motivated by what is called the smile of implied volatility.

FIGURE 7 - Gamma and shadow gamma

The shadow gamma will then take into account the movement of the delta due to a movement in the underlying price and in the volatility. More advanced shadow gamma can take even more parameters such as the trader's expectations with respect to changes in volatility and interest rates. A shadow greek is therefore a total derivative of the option price and not just a partial derivative.

1.4 Vega

The vega (vega is not a real greek letter by the way) represents the sensitivity of an option price to changes in volatility. By volatility we mean implied volatility of the option (see this link for more precisions about implied volatility : link). An increase in volatility means that the underlying price is more likely to have important variations and thus finishing in the money. The vega will therefore be positive for a long position in a call or a put. Moreover, this increase in volatility will have a greater impact on greater maturities since the volatility will be higher for a longer period and could lead to an option very in the money. One can show that calls and puts have the same vega and it is given by the following analytic formula :

$$v = \frac{\partial c}{\partial \sigma} = \frac{\partial p}{\partial \sigma} = S_0 e^{-\delta T} \sqrt{T} N'(d_1)$$

Figure 9 show the vega surface for calls and puts. The important feature is to keep in minde that the vega is an increasing function of time to maturity.

FIGURE 8 - Vega in 2D

One could want to vega hedge his portfolio if it has an important maturity or if the strike price is close to the spot or even if the portfolio is made of a lot of positions in the same side (example : a straddle has an important vega since it is both long a call and a put). In order to vega hedge, we have to find a financial product that has sensibility to volatility. Since the underlying has no sensibility with respect to the volatility we will have to use another option in most cases. Let's consider a trader with a short position in n options (called option 1) with a vega v_1 each, and that on the market another option is available (called option 2) with a vega v_2 . In order to vega hedge the position, we will have to buy (since the vega of a short position is negative) $\frac{v_1}{v_2}n$ options 2. The portfolio will then be vega hedge (again only for a limited period of time). One important point when vega hedging is not to hedge with short term options, since their vega will decrease very fast. Moreover,

FIGURE 9 - Vega surface of both call and put

one does not want to void all his profit just in order to be vega hedged, therefore we should not use ATM options, which are very costly, to vega hedge. It would make more sense to hedge with OTM options because they are cheaper. Since we are short volatility we want to be protected against increase in volatility, if we use OTM options to vega hedge, a higher volatility would mean that our OTM options will tend to act as ATM options and thus have a higher vega, our hedge will therefore be better. Finally, like when we were delta hedging, the vega hedging is only efficient locally, for small variations of the volatility. In order to be more accurate, we will have to consider the second derivative with respect to volatility : the volga.

When an exotic product has a complex sensitivity with respect to the volatility, the shape of vega could have different shapes along the term structure, those different local shapes are called vega buckets.

1.5 Volga

The volga or vega-gamma (or Vomma) is the second derivative of the option price with respect to volatility (or the derivative of the vega with respect to volatility). It allow one to take in account the convexity of the option price with respect to volatility.

For european options, only ITM and OTM options show convexity in volatility. Exotic options may have an important volga, like cliquet options or derivatives on volatility such as napoleons. The pricing of such products will thus have to take in account this convexity and the future cost of hedging this convexity.

1.6 Theta

The theta represents the sensibility of the option price to a variation in time. We already discussed the relationship between gamma and theta. One can show that the analytic formula for theta is given by :

$$\theta_{call} = \frac{\partial c}{\partial t} = -\frac{S_0 e^{-\delta T} \sigma N'(d_1)}{2\sqrt{T}} + \delta S_0 e^{-\delta T} N(d_1) - r K e^{-rT} N(d_2)$$

$$\theta_{put} = \frac{\partial p}{\partial t} = -\frac{S_0 e^{-\delta T} \sigma N'(d_1)}{2\sqrt{T}} - \delta S_0 e^{-\delta T} N(-d_1) + r K e^{-rT} N(-d_2)$$

Figures 11a and 11b show the theta for calls and puts. It is interesting to note that an deep-OTM put may have a positive theta, which means that a long position in a deep-OTM put has more value as time passes. But generally, the theta of a long position in both call or put is negative, which mean that all things being equal, the option losses value as time passes. One should be aware of this "time decay" when entering in a long postion. One should also note the non-symetric feature of the theta with respect to the underlying price.

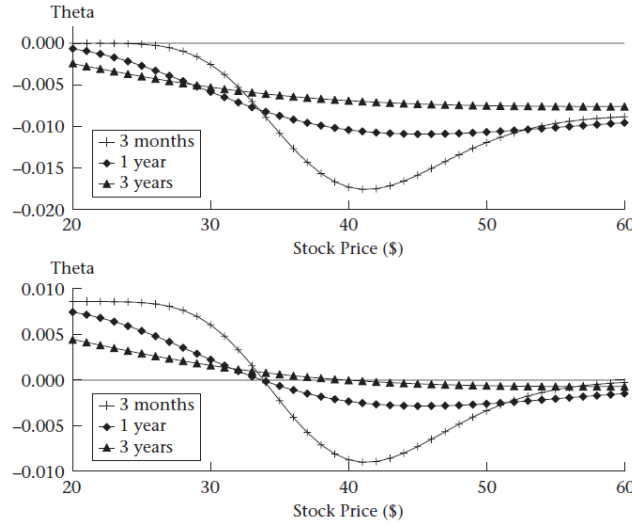

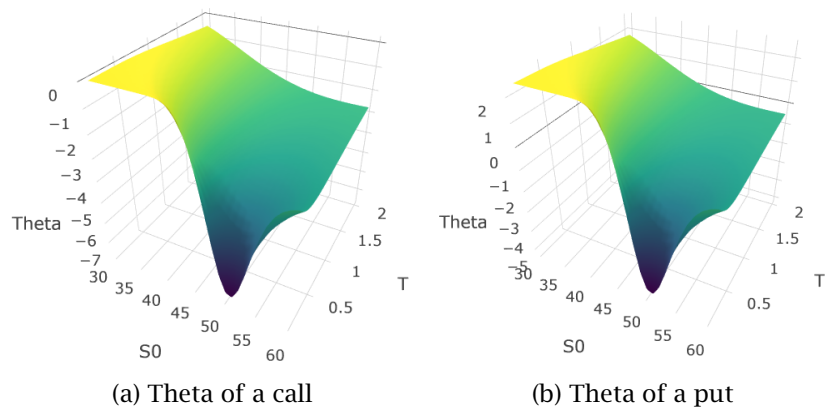

FIGURE 10 – Theta in 2D

FIGURE 11 – Theta surfaces

1.7 Rho

The rho is the sensibility of the option price to variations in interest rates. A higher interest rates means that the expected value of the underlying price will be higher (the drift of the stochastic process modeling the price is more important). Therefore a rise in interest rates is a good think for a long position in a call but a bad thing for a long position in a put and we can expect the rho of a call to be non-negative and the rho of a put to be negative. One can show that the analytic formula for rho is given by :

$$Rho_{call} = \frac{\partial c}{\partial r} = KTe^{-rT}N(d_2)$$

$$Rho_{put} = \frac{\partial p}{\partial r} = -KTe^{-rT}N(-d_2)$$

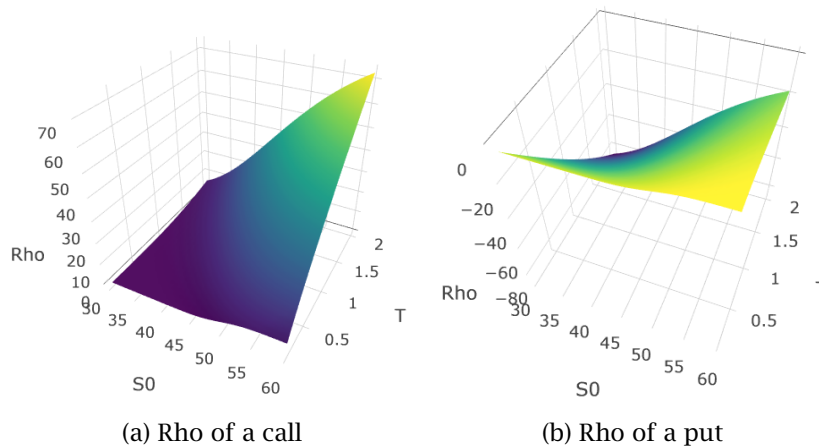

FIGURE 12 - Rho in 2D

FIGURE 13 - Rho surfaces

1.8 Omega

The delta give us an information about a rise of 1\$ in the underlying asset, but we do not have the information in percentages. This is the goal of omega, or option elasticity. The option elasticity is then defined by the delta of the option times the ratio between the underlying price and the option price f :

$$\Omega = \Delta \frac{S}{f}$$

For a call, we will always have $\Omega \geq 1$ and for a put : $\Omega \leq 0$. Figure 14, shows the elasticity for a call option with parameters $K = 40$, $\sigma = 0.3$ and $r = 0.08$:

FIGURE 14 - Omega of a call option

It is important to understand that the Omega is a measure of the implicit leverage of the option, it is thus an interesting risk metric, in order to monitor the implicit leverage of the option over its life.

The more an option is OTM, the more important the implicate leverage will be. Thus for a call, the omega is an increasing function of the strike and for a put it is a decreasing function of the strike.

The more an option is ITM, the more the option is likely to be exercised and thus the more the option looks like the underlying itself. It is then logical to find that when an option tends to be deep ITM, the omega tends to be close to 1 since the underlying has an implicit leverage of 1.

2 Other sensibilities

2.1 Volatility

Given the volatility of the underlying of an option and the option's elasticity, we can define the volatility of the option's price as follow :

$$\sigma_{option} = |\Omega| \times \sigma_{underlying}$$

As we have seen in the previous section, the elasticity of an option can be quite important if the option is OTM. Thus it is not surprising to have volatilities of 300 % or more for some options.

2.2 Risk premium

One can define the risk premium of an option with the risk premium of the underlying and the elasticity. Let y be the risk premium of the option, α the risk premium of the underlying, r the risk-free rate and Ω the elasticity of the option. We then have :

$$y - r = (\alpha - r)\Omega$$

$$y = \alpha\Omega + r(1 - \Omega)$$

2.3 Beta

Given the beta of the underlying and the option's elasticity, we can define the beta of an option as follow :

$$\beta_{option} = \Omega \times \beta_{underlying}$$

2.4 Sharpe ratio

Let α be the risk premium of the underlying, r the risk-free rate and σ the underlying's volatility. The underlying's Sharpe ratio is defined as follow :

$$\text{Sharpe ratio} = \frac{\alpha - r}{\sigma}$$

According to the previous sections, the option's volatility is $|\Omega|\sigma$ and its risk premium is $\Omega(\alpha - r)$. So the Sharpe ratio of an option is equal to the Sharpe ratio of the underlying. This is because an option is just a leveraged position in the underlying, and the leverage does not change the Sharpe ratio.

3 Numerical methods for greeks

While the Black-Scholes formula allow us to have an explicit formula for the greeks, when using a numerical method in order to price a more complicated derivative, we no longer have an explicit method for the greeks, we have to approximate. We will show how to do such a thing with the binomial tree model and with Monte-Carlo simulations. It is very important to understand the limitations of the approximation methods for the greeks. We will only present the finite differences method (see this document for other methods : [link](#)) and an application for the delta, gamma and vega (other sensitivities can be obtain with similare calculations).

3.1 Binomial tree

When using the binomial tree method for pricing a derivative we both sample the time (generally we take n steps) and the underlying price (the price can only go up or down, see figure 15). Therefore computing the delta, the gamma and the theta is quite simple using finite differences method.

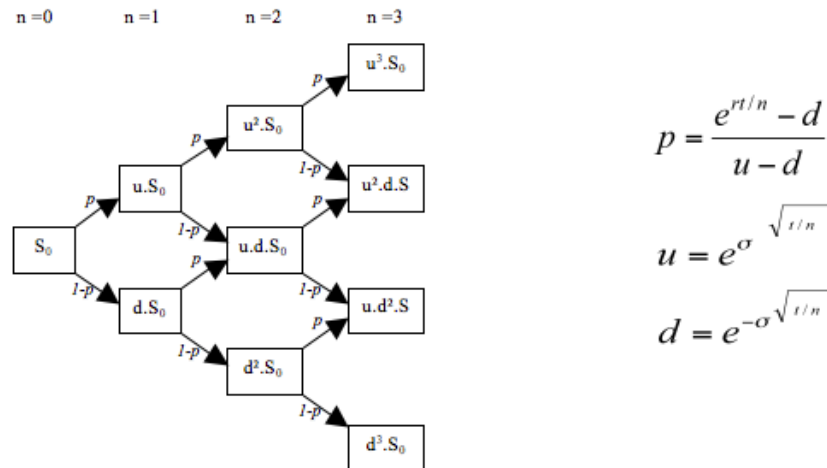

FIGURE 15 - Binomial tree pricing method

Let s_0 be the initial stock price, let u and d be the up and down probability, let Δt be the time period, let $c_u(t)$ and $c_d(t)$ be the prices of the call at time t after an up and a down movement. The finite difference

to the first order state that :

$$\Delta \approx \frac{c_u(\Delta t) - c_d(\Delta t)}{S_0 u - S_0 d}$$

In order to compute the gamma we need two value of the delta at time $2\Delta t$:

$$\Gamma \approx \frac{\frac{c_{uu}(2\Delta t) - c_{ud}(2\Delta t)}{S_0 u^2 - S_0} - \frac{c_{ud}(2\Delta t) - c_{dd}(2\Delta t)}{S_0 - S_0 d^2}}{\frac{1}{2}(S_0 u^2 - S_0 d^2)}$$

For the theta we also have all the information we need in the binomial tree : we only need two different prices of the option for the same underlying price but at different times. Thus if we take the option price at time $t = 0$ and the option price at $t = 2\Delta t$ for the path up-down (or down-up since we take a recombining tree), both options will have the same underlying price at different time, we then have :

$$\theta \approx \frac{c_{ud}(2\Delta t) - c(0)}{2\Delta t}$$

Computing the vega or the rho is a little bit more complicated since the information in the binomial tree is not enough to compute them. For the vega, we will have to compute another tree with a volatility $\sigma^* = \sigma + \Delta\sigma$. We will then have two different prices for two volatilities and the vega is given by :

$$v \approx \frac{c_{\sigma+\Delta\sigma}(0) - c_{\sigma}(0)}{\Delta\sigma}$$

The same thinking could be used to compute the rho.

We will test those approximations with a Python script (available in the annexe). The application will be for an european call so that we could compare the approximation with the Black-Scholes theoretical greeks. The results of the tests are available in the following table. We see that the approximation is quite good but as it would be predictable, the accuracy of the method decrease when we go to the second derivative, the error is bigger for the gamma.

| Greek | Theoretical value | Binomial tree approximation | Error |
|----------|-------------------|-----------------------------|---------|
| Δ | 0.63683 | 0.63680 | 0.005 % |
| Γ | 0.01876 | 0.01877 | 0.085 % |
| θ | -6.41403 | -6.41713 | 0.048 % |
| v | 37.52403 | 37.52435 | 0.001 % |

3.2 Monte-Carlo simulation

When pricing with the Monte-Carlo method, the greeks can be obtained with the same pattern that the computation of the vega for the binomial tree method : we compute a first price, then change the good parameter and compute again the price. The finite difference between the two prices will be our sensitivity (see the Python code in annexe for more details). Once again, we have to keep in mind that using this method with second or third derivative could lead to poor results. Results of this method are available in the following table.

| Greek | Theoretical value | Binomial tree approximation | Error |
|----------|-------------------|-----------------------------|---------|
| Δ | 0.63683 | 0.6377 | 0.137 % |
| Γ | 0.01876 | 0.0192 | 2.771 % |
| ν | 37.52403 | 37.5792 | 0.147 % |
